1. Comparing the Oil Shock Coefficient Across POLS, FE, and RE

The oil_pct_change coefficient across POLS and FE tells a nuanced story:

Pooled OLS

Produces no oil price variable in the continuous sense, the crisis is captured entirely through the post_crisis dummy ($\beta = 0.1175$, $p = 0.013$), which is statistically significant under standard errors and remains so under robust SE ($p = 0.009$). However, the POLS estimator is decisively rejected by the Breusch-Pagan LM test ($\chi^2 = 1954.7$, $df = 1$, $p < 2.2e-16$), confirming the presence of significant individual effects that POLS ignores. Its high R^2 of 0.717 is therefore misleading, it reflects the cross-sectional heterogeneity absorbed by policy_rate and structural differences across countries, not a genuinely well-specified relationship. Notably, ln_neer loses significance once robust standard errors are applied ($p = 0.236$), suggesting that the exchange rate coefficient in POLS is inflated by the failure to control for country-level heterogeneity.

Fixed Effects

Is the preferred estimator given the Hausman test result ($\chi^2 = 16.981$, $df = 3$, $p = 0.0007$), which rejects the Random Effects model in favour of FE by confirming that the individual effects are correlated with the regressors. Within this specification, ln_neer is entirely insignificant ($\beta = 0.021$, $p = 0.736$ under standard errors; $p = 0.929$ under robust SE), which is consistent with exchange rate variation being largely absorbed by the country fixed effects. The key finding is that the oil shock's inflationary impact operates through the structural break rather than through any continuous price movement: the post_crisis dummy carries a coefficient of $\beta = 0.04555$ ($p = 4.132e-05$ under standard errors; $p = 1.811e-05$ under robust SE), meaning the 2026 Gulf Crisis added approximately +4.56% to log CPI on average across countries, beyond what is explained by exchange rates, monetary policy, and global financial volatility. policy_rate ($\beta = 0.00849$, $p = 1.446e-12$) and vix ($\beta = 0.00286$, $p = 1.779e-06$) are both highly significant and robust, confirming that monetary tightening and financial market stress are meaningful co-determinants of inflation dynamics across this panel. The within- R^2 of 0.258 is modest by design, FE strips out all between-country variation, so it only explains variation within countries over time, which is the appropriate benchmark.

Random Effects

Includes ln_brent directly as a continuous log-level regressor rather than relying on the structural break dummy. Under standard errors, ln_brent is negative and significant ($\beta = -0.077$, $p = 8.039e-07$), but this result collapses entirely under robust standard errors ($p = 0.215$). This sign reversal and fragility is a between-estimator artefact: the RE estimator is a weighted average of within- and between-country variation, and in this sample, countries with structurally lower average oil price exposure, predominantly oil importers, tend to exhibit higher CPI growth trajectories, producing a spurious negative cross-sectional correlation that

is unrelated to the causal oil-price-to-inflation channel. The Hausman test formally confirms this inconsistency. $\ln_neer$ is also insignificant in the RE model ($\beta = -0.030$, $p = 0.618$), while $policy_rate$ ($\beta = 0.00755$, $p = 1.352e-11$) and vix ($\beta = 0.00249$, $p = 2.522e-05$) remain robustly significant, consistent with the FE estimates.

Taken together, the evidence points to a clear conclusion: the 2026 Gulf Crisis transmitted into consumer prices primarily through a discrete structural shock, captured by the $post_crisis$ dummy in the preferred FE model, rather than through a smooth, continuous pass-through from monthly oil price fluctuations. The +4.56% crisis premium on log CPI is robust to both standard and cluster-robust inference, and survives the most demanding within-country estimator. The continuous $\ln_brent$ coefficient in the RE model should not be given causal weight given both the Hausman rejection and its fragility to robust standard errors.

2. Model Selection and Diagnostic Tests

Three estimators are compared: Pooled OLS (which ignores individual heterogeneity), Fixed Effects (FE / within), and Random Effects (RE). Two formal diagnostic tests govern the choice of preferred specification.

Diagnostic Test	Null Hypothesis	Result	Decision
Breusch–Pagan LM Test	No unobserved individual effects	$\chi^2(1) = 1954.7$, $p < 0.001$	Reject H_0 — panel model required; Pooled OLS is inconsistent
Hausman Specification Test	RE is consistent (regressors uncorrelated with unit effects)	$\chi^2(3) = 16.98$, $p = 0.0007$	Reject H_0 — prefer Fixed Effects; RE is inconsistent

The Breusch–Pagan result ($\chi^2 = 1954.7$) provides overwhelming evidence of country-specific unobserved effects, likely structural differences in inflation dynamics, energy intensity, import dependence, and central-bank credibility. The Hausman test subsequently rejects the orthogonality assumption required for RE consistency ($\chi^2 = 16.98$, $p = 0.0007$), confirming that at least some regressors are correlated with these unobserved effects. The FE estimator is therefore the preferred model. RE results are retained as a sensitivity check but should not be used for primary inference.

Note on RE specification

Because oil_pct_change is a global price (identical across all countries at each date), its cross-sectional variance collapses after the RE between-transformation, causing near-zero variance and numerical singularity. The RE model therefore substitutes $\ln_brent$ (log price level) and omits $post_crisis$ (whose variation is degenerate for India and South Africa, which exit the sample before March 2026). This difference in specification partly explains divergent RE estimates and further motivates preference for the FE model.

3. Regression Results

Standard errors in parentheses. Robust SE (Arellano/HC3) used for inference throughout. Significance: *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

Variable	Pooled OLS	Fixed Effects	Random Effects	FE Robust SE
post_crisis	0.1175** (0.047)	0.0456*** (0.011)	omitted (see note)	0.0456*** (0.010), p<0.001

4. Economic Interpretation of Findings

4.1 The Post-Crisis Dummy: Did the Gulf Shock Raise Inflation?

The coefficient on post_crisis in the preferred FE model is 0.046 (robust $p < 0.001$). In log-linear terms, this implies that, controlling for exchange rates, monetary policy, and global uncertainty, the price level was approximately 4.6% higher in the post-crisis period (March 2026 onward) relative to what country-specific trends would have predicted. This is a first-pass estimate of the macroeconomic footprint of the 2026 Gulf Crisis on inflation across the sample.

The magnitude is economically meaningful. For reference, the COVID-19 supply disruption in 2020–2021 added roughly 3–5 percentage points to CPI in advanced economies over a comparable monthly window. A 4.6% uplift from a geopolitical oil shock, over just one to two months of post-crisis data, is substantial and suggests that supply-side pass-through of the Brent price spike (which reached above \$140/barrel) was rapid and broad-based.

It is important to note, however, that the dummy conflates the oil price effect with any other shock occurring simultaneously from March 2026 onward, a standard limitation of event-study dummies discussed further in Section 6.

4.2 Exchange Rate Channel (ln_neer)

In Pooled OLS, the NEER coefficient is large and negative (-0.775 , $p < 0.001$), consistent with standard theory: a stronger domestic currency reduces import costs and lowers inflation. However, this effect disappears entirely in the FE model (coefficient = 0.021 , $p = 0.736$ robust). This reversal is a textbook illustration of omitted variable bias: country fixed effects absorb the level differences in exchange rate regimes and inflation histories, revealing that within a given country over time, monthly NEER variation does not independently explain CPI fluctuations after controlling for monetary policy and global uncertainty.

4.3 Policy Rate

The policy rate enters with a positive coefficient in both Pooled OLS (0.044^{***}) and FE (0.008^{***}), which appears counterintuitive, tighter monetary policy is normally expected to reduce inflation. Two complementary explanations account for this.

First, reverse causality: central banks raise rates precisely when inflation is high. The positive coefficient likely reflects this simultaneity, rate hikes are endogenous to inflation outbreaks, not independent causes. Second, cost-push channels: higher interest rates increase firms' borrowing costs, which can be passed on to prices in the short run, generating a temporary positive effect before the contractionary demand channel dominates. Under robust standard errors, the FE policy rate coefficient loses conventional significance ($p = 0.093$), which is consistent with noisy identification under endogeneity.

4.4 Global Uncertainty (VIX)

The VIX coefficient is positive and robust across all specifications (FE: 0.0029 , robust $p < 0.001$). A one-unit increase in the VIX is associated with a 0.29% rise in the CPI. This reflects a cost-push mechanism: heightened global uncertainty disrupts supply chains, raises commodity prices, and induces precautionary stockpiling, all of which are inflationary. In the context of the 2026 Gulf Crisis — which sent global equity volatility sharply higher, the VIX channel is a meaningful secondary transmission pathway beyond the direct oil price effect.

4.5 Oil Price Channel (Note on Identification)

The primary oil shock variable (`oil_pct_change`) was dropped from the Pooled OLS output, suggesting possible collinearity issues in that specification. In the FE model, oil price variation is partially absorbed into the time dimension of the fixed effects and partially captured by the `post_crisis` dummy. The RE model's `ln_brent` coefficient of -0.077 is counterintuitive (suggesting higher oil prices reduce CPI), but becomes statistically insignificant under robust standard errors ($p = 0.215$), indicating this is likely an artefact of RE misspecification under correlated individual effects.

5. Heterogeneity: Oil Importers vs. Exporters

A central contribution of the analysis is the decomposition of the oil shock effect by trade position. The sub-sample FE regressions reveal sharply divergent dynamics across importers and exporters.

Variable	Importers (n=116)	Exporters (n=156)
Countries	Eurozone, United States, India, South Africa	Canada, Russia, Saudi Arabia
ln_neer	-0.616*** (0.121)	+0.166*** (0.060)
policy_rate	-0.027*** (0.004)	+0.011*** (0.001)
vix	-0.001 (ns) (0.001)	+0.004*** (0.001)
post_crisis	0.003 (ns) (0.020)	+0.057*** (0.011)
R ²	0.432	0.517

Several findings stand out. First, the post-crisis dummy is statistically significant only for exporters (0.057, $p < 0.001$), not importers (0.003, ns). This is initially surprising — one expects oil importers to suffer more from a price spike. A likely explanation is the fiscal and revenue windfall for exporting nations: Saudi Arabia, Russia, and Canada all benefit from higher oil revenues, which filter into domestic demand, wages, and non-traded goods prices. Importers, by contrast, may see demand compression from higher energy bills that offsets the cost-push effect in the short run.

Second, the NEER coefficient reverses sign across groups: negative for importers (-0.616), meaning currency depreciation raises inflation via import costs, consistent with standard theory. For exporters, it is positive (+0.166): when the oil price rises, exporters' currencies tend to appreciate (the petrocurrency effect), yet domestic inflation still rises because of the income and demand-side boom. This sign reversal is a powerful illustration of why pooling importers and exporters into a single regression is economically misleading.

Third, the policy rate is negative for importers (-0.027***) but positive for exporters (+0.011***). For importers, this aligns with the conventional monetary transmission mechanism — rate hikes reduce inflation. For exporters experiencing demand-pull inflationary pressure from commodity revenues, the endogeneity of rate hikes to rising inflation outweighs the contractionary effect in the short run.

Key Takeaway: The 2026 Gulf Crisis transmitted to inflation through demand-side channels in oil-exporting economies (revenue windfall → domestic price pressure) and cost-push channels in oil-importing economies. The overall post-crisis effect of +4.6% in the pooled FE model masks this fundamental asymmetry. Monetary policy implications therefore differ substantially across trade positions.

6. Limitations

1. **Short post-crisis window.** At the time of estimation, only one to two months of post-March 2026 data are available. The post-crisis dummy therefore captures an immediate, short-run effect. Full inflationary pass-through, particularly via

second-round wage effects and inflation expectations, typically materialises over 12–18 months. The reported +4.6% effect is likely an underestimate of the eventual cumulative impact, and future research should revisit this analysis with a longer time series.

2. **Endogeneity of regressors.** Several right-hand-side variables are plausibly endogenous. The policy rate responds to inflation (reverse causality). The VIX may itself respond to oil-price movements. *ln_neer* is jointly determined with inflation and capital flows. Ordinary FE does not address this endogeneity. Instrumental variables (IV-FE) or system GMM would be required for causal identification, but valid instruments for all three variables in a seven-country panel are difficult to construct.
3. **Small N, large T panel.** With only seven countries, cross-sectional variation is limited and standard errors may be imprecise even after clustering. The Hausman test and between-group comparisons (importers vs. exporters) have low degrees of freedom. Country-level conclusions cannot be drawn from a pooled FE framework.
4. **Unbalanced panel and sample attrition.** India and South Africa have shorter time series ($T = 36$ months vs. 42 for others), meaning they are absent from the post-crisis period. This confounds the importer sub-sample analysis, as the two emerging-market importers, arguably most vulnerable to an oil shock, contribute no post-crisis observations, likely biasing the importer post-crisis coefficient toward zero.
5. **Omitted variables and dummy conflation.** The *post_crisis* dummy absorbs all variation occurring from March 2026 onward, not solely oil-price effects. Concurrent events, changes in fiscal policy, supply chain disruptions, or shifts in geopolitical risk aversion, cannot be separately identified. An event-study design or a Synthetic Control Method (SCM) would offer cleaner identification of the oil-specific causal effect.
6. **Simulated scenario.** The 2026 Gulf Crisis is a hypothetical scenario constructed for pedagogical purposes. Estimates should not be interpreted as empirical forecasts of a real event. That said, the coefficients on *policy_rate*, *vix*, and the importer/exporter asymmetry are broadly consistent with the empirical literature on oil shocks (Hamilton, 2009; Kilian, 2014), lending credibility to the analytical framework.

7. Conclusion

This analysis provides three substantive contributions to understanding how geopolitical oil shocks transmit to inflation. First, it documents a statistically robust and economically significant post-crisis inflation premium of approximately 4.6% in the immediate aftermath of the 2026 Gulf Crisis, surviving country fixed effects and robust standard errors. Second, it reveals that global uncertainty (VIX) is a consistent and significant transmission channel, independent of the direct oil-price effect, underscoring the importance of financial market spillovers in an age of globally integrated commodity markets. Third, and most importantly, it

establishes a structural asymmetry between oil importers and exporters: the crisis raised inflation significantly among exporters through a demand-pull mechanism driven by commodity revenues, while importers experienced muted short-run effects, a finding that has direct implications for heterogeneous monetary policy responses.

Future work should address the endogeneity of the policy rate through an IV-FE approach, extend the analysis once a longer post-crisis time series becomes available, and consider a Synthetic Control Method to isolate the causal oil shock effect from concurrent disturbances. Expanding the panel to include a broader set of emerging-market importers, particularly those absent from the post-crisis window, would also sharpen the identification of heterogeneous transmission mechanisms.

Recommended Preferred Specification: Fixed Effects (within estimator) with Arellano–Bond HC3 robust standard errors. Post-crisis coefficient = 0.0456 (s.e. = 0.0104, $t = 4.37$, $p < 0.001$). This is the most credible estimate of the short-run inflation impact of the 2026 Gulf Crisis, conditional on the data and modelling assumptions discussed above.

Appendix: Full R Output

This appendix reproduces the complete console output of the R estimation routines exactly as generated, including all model summaries, fit statistics, effects decompositions, formal diagnostic tests, robust standard error tables, and the consolidated comparison tables.

A.7: Brent chart (Figure 1), CPI trends (Figure 2)

Figure 1. Brent Crude Oil Price: Pre and Post 2026 Gulf Crisis

Interpretation. The series shows Brent crude trading in a relatively stable band of roughly \$65–\$95 per barrel from 2023 through early 2026, with ordinary cyclical fluctuation and a mild downward drift into 2025. The vertical

dashed line marks the onset of the 2026 Gulf Crisis (the “Crisis Start”), after which the price spikes almost vertically to above \$140 per barrel. The contrast between the gentle pre-crisis variation and the abrupt post-crisis jump motivates the modelling strategy: the shock is far better characterised as a discrete structural break (the *post_crisis* dummy) than as a smooth continuous price movement, which is precisely why the dummy specification dominates the continuous *ln_brent* term in the regressions that follow.

Figure 2. Average Log CPI Trends by Country Group

Interpretation. The figure plots average log CPI for four country groups, Advanced Exporters, Advanced Importers, Emerging Exporters, and Emerging Importers, from 2023 to 2026, with the dashed vertical line marking the crisis onset. Two patterns stand out. First, the emerging-market groups (Emerging Exporter and Emerging Importer) sit on persistently higher and steeper CPI trajectories than the advanced groups, reflecting structurally higher trend inflation, exactly the kind of between-country heterogeneity the Breusch–Pagan test flags and that the fixed effects estimator absorbs. Second, all four series bend upward around the dashed line, but the steepening is visibly sharper for the exporter groups (Emerging Exporter and Advanced Exporter) than for the importers in the final months, which is the visual counterpart of the sub-sample result that the post-crisis inflation premium is significant for exporters (+0.057) but muted for importers (0.003, ns).
